Abstract

In recent years, central banks have increasingly turned to “forward guidance” as a central tool of monetary policy. Standard monetary models imply that future forward guidance has huge effects on current outcomes, and these effects grow with the horizon of the forward guidance. We present a model in which the power of forward guidance is highly sensitive to the assumption of complete markets. When agents face uninsurable income risk and borrowing constraints, a precautionary savings effect tempers their responses to changes in future interest rates. As a consequence, forward guidance has substantially less power to stimulate the economy.

1 Introduction

Forward guidance has become an increasingly important tool of monetary policy in recent years. Gurkaynak, Sack, and Swanson (2005) show that much of the surprise news about monetary policy at the time of FOMC announcements arises from signals about the central bank’s intentions about future monetary policy. In many cases, changes in the current Federal Funds rate are fully expected, and all of the *news* about monetary policy has to do with how the central bank is expected to set interest rates in the future.¹

Promises about future interest rates have been shown to have a powerful effect on the economy in standard monetary models. Eggertsson and Woodford (2003) show that a shock to the natural rate of interest that causes the economy to hit the zero lower bound on nominal interest rates induces a powerful deflationary spiral and a crippling recession. However, the recession can be entirely abated if the central bank commits from the outset to holding interest rates at the zero lower bound for a few additional quarters beyond what is justified by contemporaneous economic conditions.

Recent work argues that the magnitude of the effects of forward guidance in New Keynesian models stretches the limits of credibility. Carlstrom, Fuerst, and Paustian (2012) show that a promise by the central bank to peg interest rates below the natural rate of interest for roughly two years generates explosive dynamics for inflation and output in a workhorse New Keynesian model (the Smets and Wouters (2007) model). Del Negro, Giannoni, and Patterson (2013) refer to this phenomenon as the *forward guidance puzzle*. Along the same lines, consider an experiment whereby the central bank promises a 1 percentage point lower real interest rate *for a single quarter* at some point in the future. We show that in the plain vanilla New Keynesian model, this promise has an eighteen times greater impact on inflation when the promise pertains to interest rates 5 years in the future than when it pertains to the current interest rate.

It may seem unintuitive that an interest rate cut far in the future has a greater effect than a near-term one. To see why this arises in standard models, consider the response of consumption to a decrease in the real interest rate for a single quarter 5 years in the future. The consumption Euler equation dictates that consumption will rise immediately to a higher level and stay constant at that higher level for 5 years before returning to its normal level.² The cumulative response

¹Campbell et al. (2012) reinforce these results using a longer sample period spanning the Great Recession.

²The response is a step function because consumption growth only deviates from normal when the real interest

of consumption to the shock is therefore quite large and gets larger the further in the future the interest rate shock occurs. It is the cumulative response of consumption (with some discounting) that determines the response of current inflation in the basic New Keynesian model. So, the further in the future is the interest rate that the monetary authority announces it will change, the larger is the current response of inflation. At the zero lower bound, this large effect on inflation will lower real rates and thus create a powerful feedback loop on output.

But is it a realistic prediction of the standard model that agents increase their consumption by the same amount in response to an interest rate cut 5 years in the future as they do to a cut in the current interest rate? Many people face some risk of hitting a borrowing constraint over the next five years. This effectively shortens their planning horizon since interest rate changes in states of the world that occur after they hit a borrowing constraint are irrelevant for their current consumption plan. In addition to this, people's desire to maintain a buffer stock of saving for precautionary reasons will temper their response to future interest rate shocks. Taking full advantage of the opportunity for intertemporal substitution presented by the future interest rate change requires people to run down their assets. This is costly since it leaves them more exposed to future income shocks. As a consequence, people will trade off the gains from intertemporal substitution and the costs of running down their buffer stock of savings. As the low interest rate is further in the future, the change in assets needed to take full advantage of intertemporal substitution grows and the countervailing precautionary savings effect therefore grows stronger, tempering the effects of forward guidance.

To investigate the quantitative magnitude of these effects, we consider a general equilibrium model in which agents face uninsurable, idiosyncratic income risk and borrowing constraints. In this model, the effect of forward guidance about future interest rates on current output falls the further out in the future the interest rate change is. For forward guidance about the interest rate 5 years in the future, the effect on output and inflation is roughly 40% as large as in the standard model. For forward guidance about the interest rate 10 years in the future, the effect on current output is essentially zero.

rate deviates from normal and this only occurs in the single quarter in our experiment. Another way to see this is that the forward guidance does not change the relative price of consumption for any two dates before the date of the interest rate change. All these dates must therefore have the same level of consumption. The end-point of consumption is pinned down at the old steady state by the fact that monetary shocks have no effect on real outcomes in the long run.

Our results indicate that forward guidance is a much less effective policy tool at the zero lower bound in our incomplete markets model than it is in standard macro models. We consider a shock that lowers the natural rate of interest enough that the zero lower bound binds for 5 years and the initial fall in output is -4% in the absence of forward guidance. If we assume markets are complete (and precautionary savings thus absent), a policy of maintaining interest rates at zero for a little more than three quarters beyond what a strict inflation targeting central bank would do completely eliminates the fall in output. In contrast, in our incomplete markets model with idiosyncratic risk and borrowing constraints, the effect of this amount of forward guidance is substantially smaller and a significant recession remains.

Krusell and Smith (1998) compare the response of a complete markets and incomplete markets model to a productivity shock and find that the difference is small. In contrast, we find a large difference between the complete and incomplete markets model in response to forward guidance about real interest rates. The key difference in our experiments is the behavior of the real interest rate. Market incompleteness and household heterogeneity introduce forces that affect aggregate consumption. In the flexible price setting considered by Krusell and Smith (1998) these changes in demand are largely undone by adjustments in real interest rates.³ However, when prices are sticky and real interest rates respond sluggishly to shocks, the effects of market incompleteness and household heterogeneity on demand lead to substantial changes in output relative to the complete markets case.

Our work builds on recent papers that incorporate market incompleteness and idiosyncratic uncertainty into New Keynesian models starting with Oh and Reis (2012), Guerrieri and Lorenzoni (2015), McKay and Reis (2014), and Gornemann, Kuester, and Nakajima (2014). Related work by Auclert (2015) focuses on the redistributive effects of real interest rate changes in an incomplete markets model. We parameterize our model so as to make these redistributive effects small (since they are not the focus of our paper). Allowing for such redistributive effects can make the on-impact effects of a shock to the current interest rate quite a bit bigger than in our model. These redistributive effects are, for example, driving the large response of output to interest rates in Guerrieri and Lorenzoni (2015).

Werning (2015) shows how general equilibrium feedback effects of interest rate changes on

³We discuss this in detail in the longer working paper version of this paper (McKay, Nakamura, and Steinsson, 2015).

household income can under certain conditions result in much larger effects on output than in our model, so that the effect of forward guidance may be unchanged relative to a representative agent benchmark. To get this, Werning assumes that everyone’s income, borrowing constraints, and assets scale proportionately with aggregate income. In contrast, in our model, the extra income is received disproportionately by high income people and the shock leads incomes to rise relative to the households’ assets. Both of these features mute the strength of the general equilibrium forces that Werning emphasizes.

Several other recent papers suggest “solutions” to the forward guidance puzzle. Del Negro, Giannoni, and Patterson (2013) argue that the experiment that gives rise to the puzzle is, itself, unreasonable. They argue that it is unreasonable to assume that the central bank really can engender substantial changes in long-term interest rates, which are at the core of why the forward guidance puzzle arises. Carlstrom, Fuerst, and Paustian (2012) and Kiley (2014) show that the magnitude of the forward guidance puzzle is substantially reduced in a sticky information (as opposed to a sticky price) model. This is because the sticky information Phillips curve is less forward looking. Our solution instead yields an Euler equation that is less forward looking than in the standard model. Caballero and Farhi (2014) argue that forward guidance is less effective if the reason why the zero lower bound binds is a shortage of safe assets in the economy—a safety trap—as opposed to a deleveraging or patience shock.

The paper proceeds as follows. Section 2 explains why forward guidance is so powerful in standard New Keynesian models. Section 3 presents our incomplete markets model featuring uninsurable idiosyncratic income risk and borrowing constraints. Section 4 describes our results about the reduced power of forward guidance in our incomplete markets model relative to the standard complete markets models. Section 5 concludes.

2 Why Is Forward Guidance So Powerful?

It is useful to start with an explanation for why forward guidance is so powerful in standard monetary models. Consider the basic New Keynesian model as developed, e.g., in Woodford (2003) and Gali (2008). The implications of private sector behavior for output and inflation in this model can be described up to a linear approximation by an intertemporal “IS” equation of the form

$$x_t = \mathbb{E}_t x_{t+1} - \sigma(i_t - \mathbb{E}_t \pi_{t+1} - r_t^n), \tag{1}$$

and a Phillips curve of the form

$$\pi_t = \beta \mathbb{E}_t \pi_{t+1} + \kappa x_t. \quad (2)$$

Here, x_t denotes the output gap—i.e., the percentage difference between actual output and the natural rate of output that would prevail if prices were fully flexible— π_t denotes inflation, i_t denotes the nominal, short-term, risk-free interest rate, r_t^n denotes the natural real rate of interest—i.e., the real interest rate that would prevail if prices were fully flexible— σ denotes the intertemporal elasticity of substitution, β denotes the subjective discount factor of households, and κ is the slope of the Phillips curve which is determined by the degree of nominal and real rigidities in the economy. All variables are denoted as percentage deviations from their steady state values.

Suppose for simplicity that the monetary policy of the central bank is given by an exogenous rule for the real interest rate where the real interest rate tracks the natural real rate with some error: $r_t = i_t - \mathbb{E}_t \pi_{t+1} = r_t^n + \epsilon_{t,t-j}$. Here $\epsilon_{t,t-j}$ denotes the shock to the short term real rate in period t that becomes known in period $t - j$.⁴ Absent any monetary shocks, the real interest rate will perfectly track the natural real rate and both the output gap and inflation will be zero. Suppose we start in such a state, but then the monetary authority announces that the real interest rate will be lower by 1% for a single quarter 5 years in the future, but maintained at the natural real rate of interest in all other quarters (i.e., $\epsilon_{t+20,t} = -0.01$).⁵

Figure 1 plots the response of output to this shock (assuming for simplicity that $\sigma = 1$). Even though the real interest rate does not change until 20 quarters later, output jumps up by a full 1% immediately. Output then stays at this higher level for 20 quarters before falling back to steady state in quarter 21. To understand why output responds in this way, it is important to consider that the shock changes the relative price of consumption between quarters 20 and 21 (since it is the real interest rate in quarter 20 that changes), but leaves the relative price of consumption for any two dates before quarter 20 and any two dates after quarter 20 unchanged. This implies that consumption growth can only deviate from normal in quarter 20. In other words, the response of

⁴Given this specification of monetary policy, the model has a unique solution for which $\lim_{j \rightarrow \infty} \mathbb{E}_t x_{t+j} = 0$ and inflation is bounded. We could alternatively assume that the monetary authority sets the nominal rate according to the following rule $i_t = r_t^n + \phi \pi_t + \tilde{\epsilon}_{t,t-j}$ and $\phi > 1$. In this case, the model has a unique bounded solution (without the additional restriction that $\lim_{j \rightarrow \infty} \mathbb{E}_t x_{t+j} = 0$) and there exists a path for $\tilde{\epsilon}_{t,t-j}$ that gives the same solution as the model with monetary policy given by the exogenous path for the real rate we assume. We prefer to describe the monetary policy as an exogenous rule for the real interest rate because this simplifies our exposition substantially.

⁵Conventional specifications of monetary shocks affect real rates in more than a single quarter. But in a linear model the effects of such monetary shocks can be “decomposed” into a simple sum of the effects of changes in real rates at each horizon. In this sense one can think of our 20-quarter experiment as one component of a more complex monetary shock that affects real rates in many quarters.

Figure 1: Response of output to a one-quarter drop in the real interest rate 20 quarters in the future.

consumption must be a step function. In addition to this, the level of consumption (and output) is pinned down in the long-run by the fact that monetary shocks have no effect on real outcomes in the long run. This implies that consumption (and output) must rise by 1% immediately, so that they can fall back to steady state in quarter 21.⁶

The step-function shape of the output response in Figure 1 is determined solely by the Euler equation. The level of consumption, and therefore output, is however determined by the intertemporal budget constraint. In general equilibrium, income rises in response to this type of shock because the level of production increases in response to the increase in demand. This increase in income allows households to consume more initially without reducing consumption after period 20. We can compare this general equilibrium case to the response of a single household holding its own income fixed and also holding the actions of all other agents in the economy fixed (call this the partial equilibrium response). Figure A.1 in the appendix plots the partial equilibrium response. The partial equilibrium response is also a step function, since the same Euler equation

⁶An alternative way to see this is to solve the intertemporal IS equation—equation (1)—forward to get $x_t = -\sigma \sum_{j=0}^{\infty} \mathbb{E}_t(\hat{i}_{t+j} - \mathbb{E}_{t+j}\pi_{t+j+1} - r_{t+j}^n)$. Notice, that there is no discounting in the sum on the right hand side of this equation. This implies that the output gap will rise immediately by 1% and will stay at that higher level for the next five years and then fall back to zero all at once when the low interest rate period passes.

applies. The difference is that the increase in consumption over the first 20 quarters will cause the household to run down its wealth and imply that consumption going forward after period 20 will be permanently lower (this effect does not occur in general equilibrium due to the offsetting income rise). However, this difference is relatively small, even for a shock 20 quarters out. For this case, the partial equilibrium response of output is 91 basis points rather than the full 100 basis points in general equilibrium.

The logic described above for forward guidance 20 quarters in the future, applies for forward guidance at any horizon. As a consequence, the further out in the future the forward guidance is, the larger is the *cumulative* response of output. In the New Keynesian model, it is the the entire cumulative response of the output gap (albeit with some discounting) that determines the current response of inflation to forward guidance. To see this, it is useful to solve the Phillips curve forward to get

$$\pi_t = \kappa \sum_{j=0}^{\infty} \beta^j \mathbb{E}_t x_{t+j}. \quad (3)$$

This equation makes clear that the further in the future is the interest rate that the monetary authority announces it will change, the larger is the current response of inflation. While the response of inflation to a 1% change in the current real rate is $\kappa\sigma$, the response of inflation to a 1% change in the real rate for one quarter in the infinite future is $\kappa\sigma/(1-\beta)$. If $\beta = 0.99$, the current response of inflation to forward guidance about a single quarter in the infinite future is 100 times larger than the response of inflation to an equally large change in the current real interest rate. Figure 2 plots the response of inflation to forward guidance about interest rates at different horizons relative to the response of inflation to an equally large change in the current real interest rate. We see that the response of inflation to forward guidance about interest rates five years in the future is roughly 18 times larger than the response of inflation to an equally sized change in the current real interest rate.

To build intuition, we have assumed that there is no endogenous feedback from changes in output and inflation back onto real interest rates. Actual monetary policies are more complicated. In normal times, forward guidance about lower real interest rates in the future may be partly undone by higher real interest rates in the intervening period. On the other hand, when monetary policy is constrained by the zero lower bound on short-term nominal interest rates, the higher inflation associated with forward guidance about future interest rates will actually lower current

Figure 2: Response of current inflation to forward guidance about interest rates at different horizons relative to response to equally large change in current real interest rate.

real interest rates and this will in turn raise current output and inflation further. In this case, the outsized effects of forward guidance we describe above will be further reinforced by subsequent endogenous interest rate movements.

3 An Incomplete Markets Model with Nominal Rigidities

Section 2 shows that the huge power of far future forward guidance in standard monetary models depends crucially on the prediction of the model that the current response of output to an expected change in real interest rates in the far future (say 5 years in the future) is equally large as the response of output to a change in the current real interest rate. But is this realistic? With some probability, one will hit a borrowing constraint in the next 5 years. This effectively shortens one's planning horizon. Also, households that face uninsurable idiosyncratic income risk and borrowing constraints will be wary of running down their wealth to take advantage of the benefits of intertemporal substitution since this will reduce their ability to smooth consumption in the face of future income shocks. To analyze these effects, we develop a model with uninsurable idiosyncratic shocks to household productivity, borrowing constraints, and nominal rigidities.

3.1 The Environment

The economy is populated by a unit continuum of ex ante identical households with preferences given by

$$\mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t \left[\frac{c_{h,t}^{1-\gamma}}{1-\gamma} - \frac{\ell_{h,t}^{1+\psi}}{1+\psi} \right],$$

where $c_{h,t}$ is consumption of household h at time t and $\ell_{h,t}$ is labor supply of household h at time t . Households are endowed with stochastic idiosyncratic productivity $z_{h,t}$ that generates pre-tax labor income $W_t z_{h,t} \ell_{h,t}$, where W_t is the aggregate real wage. Each household's productivity $z_{h,t}$ follows a Markov chain with transition probabilities $\Pr(z_{h,t+1}|z_{h,t})$. We assume that the initial cross-sectional distribution of idiosyncratic productivities is equal to the ergodic distribution of this Markov chain. As the the Markov chain transition matrix is constant over time, it follows that the cross-sectional distribution of productivities is constant. We use $\Gamma^z(z)$ to denote this distribution.

In this economy, a final good is produced from intermediate inputs according to the production function

$$Y_t = \left(\int_0^1 y_{j,t}^{1/\mu} dj \right)^\mu,$$

where Y_t denotes the quantity of the final good produced at time t and $y_{j,t}$ denotes the quantity of the intermediate good produced by firm j in period t . The intermediate goods are produced using labor as an input according to the production function

$$y_{j,t} = n_{j,t},$$

where $n_{j,t}$ denotes the amount of labor hired by firm j in period t .

The market structure of this model economy combines elements that are familiar from the standard New Keynesian model with elements that are familiar from the standard incomplete markets model (Bewley, undated; Huggett, 1993; Aiyagari, 1994). While the final good is produced by a representative competitive firm, the intermediate goods are produced by monopolistically competitive firms. The intermediate goods firms face frictions in adjusting their prices that imply that they can only update their prices with probability θ per period as in Calvo (1983). These firms are controlled by a risk-neutral manager who discounts future profits at rate β . Whatever profits are produced are paid out immediately to the households with each household receiving an equal share D_t . Households cannot trade their stakes in the firms.

Households trade a risk-free real bond with real interest r_t between periods t and $t+1$. Borrowing constraints prevent these households from taking negative bond positions. There is a stock of government debt outstanding with real face value B . The government raises tax revenue to finance interest payments on this debt. These taxes are collected by taxing households according to their labor productivity $z_{h,t}$. Let $\tau_t \bar{\tau}(z_{h,t})$ be the tax paid by a household h in period t . By levying the taxes on labor productivity, which is exogenous, the tax does not distort household decisions in the same way that a lump-sum tax does not. At the same time, the dependence of the tax on $z_{h,t}$ allows us to manipulate the cross-sectional correlation of tax payments and earnings.

We assume that the government runs a balanced budget so as to maintain a stable level of debt in each period. The government budget constraint is

$$\frac{B}{1+r_t} + \sum_z \Gamma^z(z) \tau_t \bar{\tau}(z) = B. \quad (4)$$

To illustrate our main results about the power of forward guidance, we will consider several monetary policy experiments involving somewhat different specifications of monetary policy. These are described in Section 4. The relationship between the real interest rate, the nominal interest rate i_t , and inflation π_t is given by the Fisher relation in the usual way

$$1+r_t = \frac{1+i_t}{1+\pi_{t+1}} \quad (5)$$

where $\pi_{t+1} \equiv P_{t+1}/P_t - 1$ and P_t is the aggregate price level.

3.2 Decision Problems

The decision problem faced by the households in the economy is

$$V_t(b_{h,t}, z_{h,t}) = \max_{c_{h,t}, b_{h,t+1}, \ell_{h,t}} \left\{ \frac{c_{h,t}^{1-\gamma}}{1-\gamma} - \frac{\ell_{h,t}^{1+\psi}}{1+\psi} + \beta \sum_{z_{h,t+1}} \Pr(z_{h,t+1}|z_{h,t}) V_{t+1}(b_{h,t+1}, z_{h,t+1}) \right\}$$

subject to

$$\begin{aligned} c_{h,t} + \frac{b_{h,t+1}}{1+r_t} &= b_{h,t} + W_t z_{h,t} \ell_{h,t} - \tau_t \bar{\tau}(z_{h,t}) + D_t \\ b_{h,t+1} &\geq 0. \end{aligned}$$

Let $c_t(b, z)$ be the decision rule for $c_{h,t}$, $g_t(b, z)$ be the decision rule for household bond holdings $b_{h,t+1}$, and $\ell_t(b, z)$ be the decision rule for $\ell_{h,t}$. These policy rules vary over time in response to aggregate events that affect current or future prices, taxes, or dividends.

The final goods producer's cost minimization problem implies that

$$y_{j,t} = \left(\frac{p_{j,t}}{P_t} \right)^{\mu/(1-\mu)} Y_t, \quad (6)$$

where $p_{j,t}$ is the price charged by firm j in period t and the aggregate price index is given by

$$P_t = \left(\int_0^1 p_{j,t}^{1/(1-\mu)} dj \right)^{1-\mu}.$$

When an intermediate goods producer updates its price it solves

$$\max_{p_t^*, \{y_{j,s}, n_{j,s}\}_{s=t}^{\infty}} \sum_{s=t}^{\infty} \beta^{s-t} (1-\theta)^{s-t} \left(\frac{p_t^*}{P_s} y_{j,s} - W_s n_{j,s} \right)$$

subject to

$$y_{j,s} = \left(\frac{p_t^*}{P_s} \right)^{\mu/(1-\mu)} Y_s,$$

$$y_{j,s} = n_{j,s},$$

where p_t^* is the price set by firms who are able to update their price at date t .

The solution to this problem satisfies

$$\frac{p_t^*}{P_t} = \frac{\sum_{s=t}^{\infty} \beta^{s-t} (1-\theta)^{s-t} \left(\frac{P_t}{P_s} \right)^{\mu/(1-\mu)} Y_s \mu W_s}{\sum_{s=t}^{\infty} \beta^{s-t} (1-\theta)^{s-t} \left(\frac{P_t}{P_s} \right)^{1/(1-\mu)} Y_s}. \quad (7)$$

3.3 Equilibrium

Let $\Gamma_t(b, z)$ be the distribution of households over idiosyncratic states at date t . This distribution evolves according to

$$\Gamma_{t+1}(\mathcal{B}, z') = \int_{\{(b,z): g_t(b,z) \in \mathcal{B}\}} \Pr(z'|z) d\Gamma_t(b, z) \quad (8)$$

for all sets $\mathcal{B} \subset \mathbb{R}$.

As a result of nominal rigidities, price dispersion will result in some loss of efficiency. Integrating both sides of (6) across firms and using $y_{j,t} = n_{j,t}$ yields an aggregate production function

$$S_t Y_t = \int n_{j,t} dj \equiv N_t, \quad (9)$$

where N_t is aggregate labor demand and $S_t \equiv \int_0^1 \left(\frac{p_{j,t}}{P_t} \right)^{\mu/(1-\mu)} dj$ reflects the efficiency loss due to price dispersion. S_t evolves according to

$$S_{t+1} = (1-\theta) S_t (1 + \pi_{t+1})^{-\mu/(1-\mu)} + \theta \left(\frac{p_{t+1}^*}{P_{t+1}} \right)^{\mu/(1-\mu)}. \quad (10)$$

Inflation can be written as a function of the relative price selected by firms that update their prices

$$1 + \pi_t = \left(\frac{1 - \theta}{1 - \theta \left(\frac{p_t^*}{P_t} \right)^{1/(1-\mu)}} \right)^{1-\mu}. \quad (11)$$

Aggregate labor supply is given by

$$L_t \equiv \int z \ell_t(b, z) d\Gamma(b, z). \quad (12)$$

and labor market clearing requires

$$L_t = N_t. \quad (13)$$

Bond market clearing requires

$$B = \int g_t(b, z) d\Gamma_t(b, z). \quad (14)$$

The aggregate dividend paid by the intermediate goods firms is

$$D_t = Y_t - W_t N_t. \quad (15)$$

Finally, integrating across the household budget constraints and using the government budget constraint and equation (15) gives

$$C_t = Y_t \quad (16)$$

as the aggregate resource constraint, where $C_t \equiv \int c_t(b, z) d\Gamma_t(b, z)$.

An equilibrium of this economy consists of decision rules and value functions $\{g_t(b, z), \ell_t(b, z), V_t(b, z)\}_{t=0}^{\infty}$ that solve the household's problem, distributions $\{\Gamma_t(b, z)\}_{t=0}^{\infty}$ that evolve according to (8). In addition, an equilibrium involves sequences $\{C_t, L_t, N_t, Y_t, D_t, i_t, W_t, \pi_t, r_t, p_t^*/P_t, S_t, \tau_t\}_{t=0}^{\infty}$, that satisfy the definitions of C_t and L_t and equations (4), (5), (7), (9), (10), (11), (13), (15), (16), and a monetary policy rule as described in section 4.

The main difference between this model and the model discussed in section 2 is the fact that markets are incomplete. If we modified this model to have complete markets and then linearized the equilibrium conditions, we would get the model in section 2. The introduction of incomplete markets yields a role for precautionary savings and it implies that redistribution of wealth across agents can affect the evolution of aggregate output. The fact that the present model is not linearized also implies that price dispersion affects equilibrium outcomes.

Table 1: Baseline Calibration

Parameter	Description	Value	Target
β	discount factor	0.986	2% annual interest rate
γ	risk aversion	2	
$1/\psi$	Frisch elasticity	1/2	Chetty (2012)
B	supply of assets	$1.4 \times$ annual GDP	aggregate liquid assets (see text)
μ	markup	1.2	Christiano, Eichenbaum, and Rebelo (2011)
θ	price revision rate	0.15	Christiano, Eichenbaum, and Rebelo (2011)

3.4 Calibration

Our model period is one quarter and our calibration is summarized in Table 1. We fix the steady state real interest rate at 2% annually and adjust the discount factor to match this.⁷ We set the coefficient of risk aversion to 2. We set the Frisch elasticity of labor supply to 1/2, which is in line with the findings of Chetty (2012). In our baseline calibration we set the supply of government bonds, B , to match the ratio of aggregate liquid assets to GDP. We calculate liquid assets from aggregate household balance sheets reported in the Flow of Funds Accounts and take the average ratio over the period 1970 to 2013.⁸ Our choice to calibrate the aggregate supply of assets to match liquid assets is motivated by the view that much of household net worth is illiquid and therefore not easily used for consumption smoothing and intertemporal substitution.⁹ In a sensitivity analysis we also consider a calibration in which we match aggregate household net worth, which we also calculate from the Flow of Funds Accounts (described below).

For our choices of the desired markup of intermediate firms, μ , and probability of maintaining a fixed price, θ , we follow Christiano, Eichenbaum, and Rebelo (2011) and set $\mu = 1.2$ and $\theta = 0.15$.

⁷We use the term “steady state” to refer to the stationary equilibrium in which aggregate quantities and prices are constant and inflation is zero.

⁸We use the same definition of liquid assets as Guerrieri and Lorenzoni (2015). Flow of Funds Table B.100 Lines 10 (deposits), 17 (treasury securities), 18 (agency and GSE securities), 19 (municipal securities), 20 (corporate and foreign bonds), 24 (corporate equities), 25 (mutual fund shares).

⁹Kaplan and Violante (2014) present a lifecycle savings model with liquid and illiquid assets and show that the illiquidity of household net worth leads to stronger and more realistic consumption responses to transitory income fluctuations.

The implied degree of price stickiness is on the high side of values used in the business cycle literature. This tends to reduce the size of the effects we find on inflation since it makes inflation less sensitive to changes in current marginal costs. In the exercises we do where the zero lower bound on nominal interest rates binds, this also tends to reduce the size of the effects on output since the smaller effects on inflation translate into smaller effects on real interest rates (Werning, 2012).

We calibrate the idiosyncratic wage risk to the persistent component of the estimated wage process in Floden and Lindé (2001).¹⁰ The estimates of Floden and Lindé are for an AR(1) with annual observations of log residual wages after the effects of age, education, and occupation have been removed. Floden and Lindé find an autoregressive coefficient of 0.9136 and an innovation variance of 0.0426. We convert these estimates to parameters of a quarterly AR(1) process for log wages by simulating the quarterly process and aggregating to annual observations. We find the parameters of the quarterly process such that estimating an AR(1) on the simulated annual data reproduces the Floden and Lindé estimates, which results in an autoregressive coefficient of 0.966 and an innovation variance of 0.017. We discretize the resulting AR(1) process for log wages to a three-point Markov chain using the Rouwenhorst (1995) method.¹¹

Finally, to capture the fact that the bulk of tax payments are made by those with high earnings we set $\bar{\tau}(z)$ to be positive only for the highest z . Since households are heterogeneous in the incomplete markets model, their MPCs differ widely. Households with little wealth have high MPCs, while households with a great deal of wealth have much lower MPCs. As a consequence, wealth redistribution matters for aggregate consumption dynamics. For example, a reallocation of income from high to low net worth households leads to higher consumption demand, all else equal. One way in which this shows up in our model is that a reduction in real interest rates will lead to a redistribution from savers to borrowers.¹² In our model, households are savers and the government is the borrower. Our (realistic) assumption that taxes are paid mostly by the rich leads these redistribution effects to be relatively small as those households with many savings tend to be

¹⁰While it is common to include a transitory income shock in empirical models of wage dynamics we do not include such transitory shocks in our analysis because their impact on the quantitative results will be small as these shocks are easily smoothed by virtue of being transitory.

¹¹Kopecky and Suen (2010) prove that the Rouwenhorst method can match the conditional and unconditional mean and variance, and the first-order autocorrelation of any stationary AR(1) process.

¹²Auclert (2015) studies this redistribution channel of monetary policy in detail and shows that the redistribution depends on the agents' unhedged interest rate exposures.

those with the greatest tax liabilities, which absorb the change in the government’s debt service costs.

3.5 Alternative Calibrations

Our baseline calibration potentially implies too little volatility in household earnings. Guvenen, Ozkan, and Song (2014) report the standard deviation of the distribution of five-year earnings growth rates to be 0.73.¹³ Our model calibrated as described above implies this standard deviation is only 0.53.

We therefore consider an alternative calibration in which we raise the variance of the productivity shocks in the model so that our model matches this moment of the five-year earnings growth rate distribution. Doing so requires raising the variance of the idiosyncratic productivity innovation from 0.017 to 0.033. With more risk, the larger precautionary savings motive raises the total demand for assets by households. In this calibration we, thus, reduce the discount factor so that the model is again consistent with the total supply of assets and a 2% annual interest rate. This requires a discount factor of 0.978. We refer to this as the High Risk calibration.

We also explore the extent to which our results depend on the average level of assets in the economy. With more assets, households will generally have more self-insurance and therefore will be less concerned with running down their assets. To explore this possibility we consider an alternative calibration in which we raise the supply of government debt, B , so that the average wealth in the economy is equal to the aggregate net worth of the household sector from the Flow of Funds, including both liquid and illiquid wealth.¹⁴ This yields a ratio of assets to annual GDP of 3.79. With a larger supply of assets, bond market clearing requires that households are more patient so as to increase the demand for assets at a given interest rate. In this calibration, we set the discount factor to 0.992 to be able to match a 2% annual interest rate. We refer to this as the High Asset calibration.

Finally we consider a case where we increase both the supply of assets and the extent of risk that households face. In this case we match a ratio of assets to GDP of 3.79 and the standard deviation of five-year earnings growth rates of 0.73. The discount factor needed to match a 2%

¹³This value is the average across years of the values reported in Table A8 of Guvenen, Ozkan, and Song (2014).

¹⁴Here we use the ratio of household net worth to GDP averaged over 1970 to 2013. Household net worth is taken from Table B.100 Line 42.

annual interest rate is 0.990. We refer to this as the High Risk and Asset calibration.

3.6 Computation

In Section 4, we compute the perfect foresight transition paths of the economy in response to monetary policy and demand shocks. We assume that the economy begins in the steady state and returns to steady state after 250 quarters. We begin by guessing paths for all aggregate quantities and prices. We can then verify whether this guess is an equilibrium by checking that the definition of an equilibrium given above is satisfied. Part of this step involves solving and simulating the households problem at the guessed prices. We solve the household's problem by iterating on the Euler equation backwards through time using the endogenous gridpoint method of Carroll (2006) to compute the policy rules for each period of the transition. We then simulate the population of households forwards through time using a non-stochastic simulation algorithm to compute the distribution of wealth at each date. We can then compute aggregate consumption, labor supply, and bond holdings using the policy rules and distribution of wealth for each date. If our guess is not an equilibrium we update it to a new guess that is closer to an equilibrium. We generate the new guess of prices and aggregate quantities by making use of an auxiliary model that approximates the aggregate behavior of the incomplete markets households and then solving for an equilibrium under this approximating model. We perform this step using a version of Newton's method. We provide additional details of the computational methods in Appendix A.

4 Results

Our main result is that the power of forward guidance is substantially muted in the incomplete markets model we present in Section 3 relative to the standard complete-markets New Keynesian model. To illustrate this, we first consider a simple policy experiment: suppose the central bank promises a 50 basis point (i.e., 2% annualized) decrease in the real interest rate for a single quarter 5 years in the future.¹⁵

Figure 3 plots the response of output to this shock in our incomplete markets model and, for comparison, in the complete markets version of this model. As we discuss in section 2, the response of output under complete markets is a step function: Output immediately jumps up by 25 basis

¹⁵As in Section 2, we assume here that the monetary authority sets an exogenous path for the real interest rate.

Figure 3: Response of output to 50 basis point forward guidance about the real interest rate in quarter 20 (with real interest rates in all other quarters unchanged).

points and remains at that elevated level for 20 quarters before returning to steady state (recall that the IES is $1/2$). In contrast, in the incomplete markets model the initial increase in output is only about 40% as large. Output then gradually rises as the interest rate decrease gets closer. But even in the period right before the interest rate decrease, the increase in output is substantially smaller than under complete markets.

To understand why the response of output is muted under incomplete markets, it is useful to start by considering how a single household would respond to this type of shock in partial equilibrium (i.e., if its income was unaffected by the shock). As we discuss in the introduction, this household will increase its consumption, but by less than it would under complete markets. This is because it is loath to run down its buffer stock of savings since a smaller buffer stock will leave the household more exposed to future idiosyncratic shocks to income. The household will therefore trade-off the cost of a lower buffer stock with the gains from intertemporal substitution. This contrasts with the complete markets case where it poses no concern for households to run down their wealth, since they are fully insured against all shocks, and as a consequence households take full advantage of opportunities to intertemporally substitute.

In general equilibrium, the increased consumption demand results in higher income (since $C_t =$

Y_t in equilibrium). The extra income yields a further boost to the household's consumption demand implying that the general equilibrium response is larger than the partial equilibrium response. In our model, this general equilibrium boost is relatively small implying that the general equilibrium response is similar in magnitude to the partial equilibrium response (see Figure A.2 in the appendix).

Another difference between the complete markets response and the incomplete markets response in Figure 3 is that, after the interest rate change passes, output falls below steady state for some time in the incomplete markets case. The reason for this is that the interest rate shock leads to a redistribution of wealth away from households with high marginal propensities to consume and towards households with low marginal propensities to consume (MPC). This wealth redistribution lowers aggregate demand (and therefore output) for some time until the distribution of wealth has had time to converge back to steady state.¹⁶

Figure 4 plots the response of inflation to this same shock. The five year output boom induced by the forward guidance about real interest rates leads to a large inflation response in the complete markets case. Since the output boom is much smaller in the incomplete markets model, the rise in inflation is also much smaller. The initial response of inflation in the incomplete markets model is again only about 40% as large as in the complete markets model.

Are these responses symmetric for interest rate increases versus decreases? Above, we consider the response of the economy to a decrease in interest rates five years in the future. We get very similar results if we instead consider an equally large increase in interest rates five years in the future. The immediate effect on output is a drop of 12 basis points, while output rises by about 10 basis points in the case of a decrease (Figure 3). The immediate effect on inflation is a drop of 28 basis points, while inflation rises by about 30 basis points in the case of decrease (Figure 4).¹⁷

¹⁶There are two reasons why the interest rate shock leads to a redistribution towards households with low MPCs (which tend to be the high productivity households). First, the fall in interest rates implies that the government needs less tax revenue in period 20 to pay the interest on the debt. Since the high productivity households pay the tax, they benefit from this fall in taxes. If these same households owned all the assets, their asset income would fall by an equal amount. The high productivity households own most of the assets but not all. So, on net, they benefit from the fall in interest rates. Second, the boom in output that the fall in interest rates causes leads wages to rise more than firm dividends. Since a larger fraction of the income of high productivity households is wage income, this also disproportionately benefits the high productivity households.

¹⁷It may seem puzzling that the absolute size of the output response is larger for the interest rate increase, but the ranking is reversed for the inflation response. Both interest rate increases and decreases yield an increase in price dispersion (because they both yield non-zero inflation). This implies that more labor is needed to produce the amount of output demanded, which raises wages in both cases and pushes inflation up, reversing the relative rankings.

Figure 4: Response of inflation to 50 basis point forward guidance about the real interest rate in quarter 20 (with real interest rates in all other quarters unchanged).

4.1 Dependence on Horizon of Forward Guidance

The difference between the complete and incomplete markets models grows with the horizon of the interest rate shock. Figure 5 plots the initial response of output to 50 basis point forward guidance about the real interest rate in a single quarter as the horizon of that single quarter changes from one to 40 quarters.¹⁸

In the complete markets model, output always rises by 25 basis points, regardless of the horizon of the forward guidance. In contrast, in the incomplete markets model, the effect is only about 20 basis points for an announcement about the real interest rate next quarter and falls monotonically thereafter. It is roughly 10 basis points for an announcement about the real interest rate 5 years ahead; and essentially zero for an announcement about the real interest rate 10 years ahead.

Intuitively, the probability of hitting a borrowing constraint before the interest rate change rises with the length of time until the interest rate change occurs. For this reason, the benefit of responding falls. In addition, the cost of responding rises since the amount the household would

¹⁸For example, the points at horizon 20 in Figure 5 are the first points on each line in Figure 3. And the points at horizon 10 in Figure 5 are the initial response of output in the two models if the central bank announces that it will lower the real interest rate by 50 basis points for a single quarter 10 quarters in the future.

Figure 5: Initial response of output to 50 basis point forward guidance about the real interest rate for a single quarter at different horizons.

need to run down its assets to take full advantage of the opportunity to intertemporally substitute gets larger and larger. Together, these forces imply that eventually the benefits from intertemporal substitution are simply too small to make it worth it for households to incur the costs associated with running down their buffer-stock savings.

In section 2, we show how the immediate full response of consumption under complete markets to an interest rate change at any future horizon arises because the response of current consumption is a function of an undiscounted sum of log changes in future real interest rates. In contrast, in our incomplete markets model, consumption behaves as though there is a “discount factor” on future consumption in the Euler equation which discounts the effects of real interest rate changes more and more the further in the future they are.¹⁹ The extent of this type of discounting depends on the nature of the incomplete markets model, and the policy experiment. We explore below how this discounting is dependent on the amount of risk households face and the amount of assets they

¹⁹In the working paper version of this paper (McKay, Nakamura, and Steinsson, 2015), we present a simple model with incomplete markets and unemployment risk which yields a log-linearized Euler equation of the form $\hat{C}_t = \alpha \mathbb{E}_t \hat{C}_{t+1} - \gamma^{-1} (i_t - \mathbb{E}_t \pi_{t+1} - r_t^n)$, where hats on variables denote percent deviations from steady state. This Euler equation differs from the standard Euler equation due the “discount factor” α in front of the $\mathbb{E}_t \hat{C}_{t+1}$ term. We show that this simple model can generate very similar responses to forward guidance to the incomplete markets model we consider in this section.

Figure 6: Initial response of inflation to 50 basis point forward guidance about the real interest rate for a single quarter at different horizons.

have to self-insure.

The results for inflation are even starker. Figure 6 plots the initial response of inflation to forward guidance about the real interest rate at different horizons. In the complete markets model, the response of inflation rises explosively with the horizon of the forward guidance.²⁰ In the incomplete markets model, in contrast, the inflation response is smaller to start out with, grows more slowly, and therefore generates very different results at long horizons.

4.2 Results for Alternative Calibrations

Table 2 presents the results of the forward guidance experiment described above for our baseline incomplete markets model as well as for several alternative calibrations of our incomplete markets model. We also present the results for the the complete markets version of our model, for compar-

²⁰There is a powerful feedback loop in our non-linear model. High inflation leads to an increase in price dispersion, which results in loss of efficiency. Workers must then work harder to produce the output that households demand. To induce workers to work more, wages must rise leading to more inflation. For small amounts of inflation these forces are not important, but if inflation remains elevated for long enough these dynamics lead to a sharp enough increase in wages and relative prices that the model solution can no longer be computed accurately. Interestingly, inflation itself asymptotes to a finite value because, in the non-linear New Keynesian model, no matter how high the current desired price of adjusting firms is, inflation can only asymptote to a certain level, because demand (and the products weight in the price index) falls with the relative price of adjusting firms. See Ascari (2004) for a very related discussion.

Table 2: Power of 20 Quarter Ahead Forward Guidance

	Initial Responses of	
	Output	Inflation
Baseline	10.3	29.8
High Risk	4.8	23.8
High Asset	14.5	36.2
High Risk and Asset	11.6	33.8
Complete Markets	25.0	74.3

Initial response of output and inflation (in basis points) to forward guidance that reduces the expected real interest rate 20 quarters ahead by 50 basis point for four different calibrations of our incomplete markets model.

ison. In each case, we present the initial response of output and inflation to 50 basis point forward guidance about the real interest rate for a single quarter 5 years in the future.

The High Risk calibration features greater uninsurable risk than our baseline calibration. We roughly double the volatility of idiosyncratic productivity shocks relative to our baseline calibration, allowing us to match recent evidence on the volatility of earnings growth from Guvenen, Ozkan, and Song (2014). This boosts the precautionary savings motive and further reduces the power of forward guidance relative to the complete markets benchmark. The response of output in this case is only about 20% of the complete markets benchmark and the response of inflation only about 32% of the complete markets benchmark.

In the High Asset calibration, we set the ratio of assets to GDP in the model to be almost three times higher than in our baseline calibration (3.79 versus 1.4). We do this to match the ratio of total net worth in the economy to GDP (as opposed to total liquid assets as in our baseline calibration). Increasing the quantity of available assets in the economy increases the size of the precautionary savings buffers available to households and thus reduces their reluctance to engage in intertemporal substitution. This change therefore moves the incomplete markets model closer to the complete markets benchmark. The output response rises to 58% of the complete markets benchmark, while the inflation effect rises to 49%.²¹

²¹One might ask how adding unsecured debt would affect our results. We have considered a case in which the

We also consider a High Risk and Asset calibration with both of the above-mentioned alternative parameter values. These two modifications largely offset each other. As a consequence, the results lie between the two calibrations described above and close to the baseline calibration. The response of output in this calibration is 46% of the complete markets benchmark, while the response of inflation is 45% of the complete markets benchmark.

These alternative calibrations demonstrate that, with more risk and less self-insurance, the effects of precautionary savings and credit constraints become more pronounced. There are several reasons to believe that our baseline calibration understates the importance of these forces. In our baseline calibration, the fraction of agents that are constrained in steady state is 13% implying that 87% of households have positive liquid assets. Kaplan, Violante, and Weidner (2014) present estimates from the U.S. Survey of Consumer Finances that 75% of U.S. households have positive liquid assets. On this metric, therefore, our baseline calibration understates the fraction of households with low liquid assets relative to the U.S. data. A related statistic is the average marginal propensity to consume (MPC). In our baseline calibration the average MPC is only 12%, and even in our High Risk calibration it rises only to 14%. In contrast, a substantial amount of empirical evidence suggests larger values for the average MPC, with many studies estimating values close to 20%.²² On the basis of these statistics, one might argue for calibrations in which households are more credit constrained than in the calibrations we have considered. Such a calibration would likely further amplify the effects we emphasize regarding the differences between the complete and incomplete markets models.

4.3 Zero Lower Bound Analysis

In recent years, risk-free nominal interest rates around the world have hit zero. At the zero lower bound (ZLB), forward guidance has become an indispensable policy tool, since it is no longer

amount of assets in the model is calibrated as in our baseline case but we relax the borrowing constraint by allowing households to borrow up to five times average monthly labor income. Figure 2 of Kaplan, Violante, and Weidner (2014) indicates that very few households have unsecured debt that is larger than five times monthly income. This calibration yields results that are very similar to our baseline case (an initial output response of 10.9bp versus 10.3bp in our baseline case).

²²Parker (1999) estimates that household spend 20% of increases in disposable income when they hit the Social Security tax cap. Johnson, Parker, and Souleles (2006) estimate that households spent 20-40% of tax rebate checks they received in 2001, and Parker et al. (2013) estimate that households spent 12-30% of tax rebate checks they received in 2008. These studies as well as most others on this topic consider anticipated changes in income. They therefore provide a lower bound for responses to unanticipated changes in income. See Jappelli and Pistaferri (2010) for an excellent recent survey of the literature on the response of consumption to changes in income.

possible to implement monetary policy via the current policy rate. Eggertsson and Woodford (2003) show how a persistent shock to the natural interest rate that causes the economy to hit the ZLB can provoke a massive recession if the central bank does not engage in unconventional monetary policy. They show, however, that the recession can be fully abated by a relatively modest amount of forward guidance about future interest rates.

Our conclusions above suggest that forward guidance may not be as powerful at the ZLB in our incomplete markets model. To investigate this question, we follow Eggertsson and Woodford (2003) in assuming that the ZLB is brought on by a temporary shock to the subjective discount factor of households in the economy that depresses the natural rate of interest below zero. In other words, we now consider a case where the discount factor can vary over time. The specific shock we consider is an increase in the discount factor that lasts for a known number of quarters and then reverts to normal.²³ We choose the size and persistence of the shock so that the initial output decline is 4% and the ZLB binds for 20 quarters under a naive monetary policy (described below).²⁴

We consider two alternative monetary policies. First, we consider a policy where the central bank sets the nominal interest rate equal to a simplified Taylor rule whenever this yields an interest rate greater than zero, and, otherwise, sets the nominal rate to zero: $i_t = \max[0, \bar{r} + \phi\pi_t]$, where $\phi = 1.5$ and \bar{r} is the steady state real interest rate. We refer to this policy as the “naive” policy. We also consider an “extended” policy whereby the central bank sets the nominal rate to zero for several additional quarters beyond what is implied by the naive policy and then reverts back to the policy rule. We choose the length of the additional monetary stimulus to fully eliminate the initial fall in output in the complete markets model.

Figure 7 shows that forward guidance is substantially less powerful at the ZLB in the incomplete markets model than in the standard New Keynesian model. The bottom two lines show the path of output under the naive monetary policy for the complete and incomplete markets cases; while

²³Our shock differs from the shock considered in Eggertsson and Woodford (2003) in that its persistence is known, implying that agents have perfect foresight about the evolution of the aggregate economy. Eggertsson and Woodford (2003) consider a shock that reverts back to normal with constant probability each period. Clearly, both formulations are approximations. Eggertsson and Woodford’s formulation abstracts from time-variation in the probability of the ZLB period ending, while our framework abstracts from uncertainty about when it will end. However, the incomplete markets model is more difficult to solve computationally without the assumption of perfect foresight for aggregate shocks.

²⁴Hitting these targets requires slightly different calibrations of the discount factor shock in the complete versus the incomplete markets model: it corresponds to a decline in the natural rate of 16.4 basis points in the incomplete markets model, but only 14.8 basis points in the complete markets model. In each case, the duration of the shock is 33 quarters.

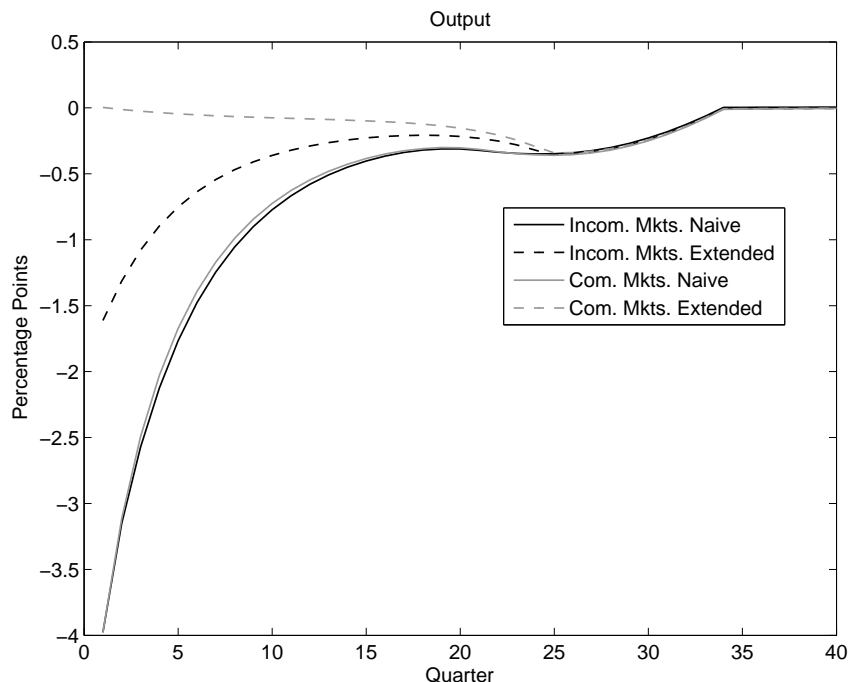

Figure 7: Response of output to the ZLB shock.

the top two lines show the effects of the extended monetary policy in these two cases. While the extended monetary policy fully eliminates the recession in the complete markets case, a substantial recession remains in the incomplete markets model. Figure 8 shows the implications for inflation: the extended policy is much more successful in preventing deflation in the complete markets model versus the incomplete markets model. While the initial deflation is only about 30 basis points in the complete markets case, it is more than 100 basis points in the incomplete markets case. The fact that inflation is lower in the incomplete markets case implies that real interest rates are higher (since nominal rates are stuck at zero). This contributes to the larger fall in output.

Figure 9 plots the implications of the naive and extended monetary policies for the nominal interest rate. Under the naive policy the ZLB binds for 20 quarters and then rises gradually to its steady state value of 50 basis points. Under the extended policy, the nominal interest rate remains at zero for 23 quarters (an additional 3 quarters), and interest rates are somewhat lower in quarter 24 than the naive policy implies (this partial stimulus in the 24th quarter is what is needed to exactly eliminate the initial fall in output due to the shock). The difference between the dashed and solid lines, thus, indicates the amount of additional stimulus provided by the extended policy.

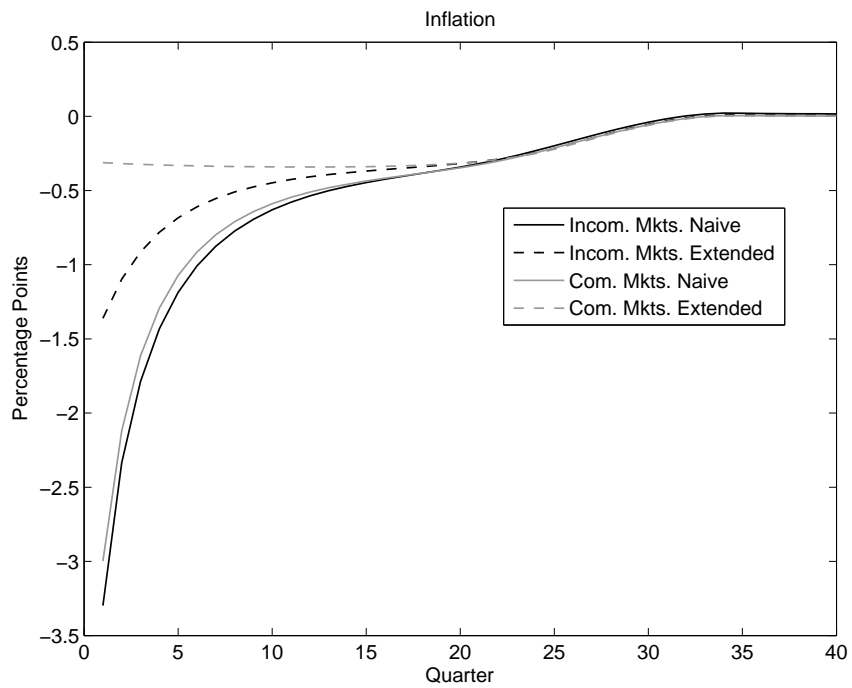

Figure 8: Response of inflation to the ZLB shock.

Figure 9: Response of nominal interest rate to the ZLB shock.

5 Conclusion

We study the effects of forward guidance about monetary policy. We do this in a standard New Keynesian model augmented with uninsurable income risk and borrowing constraints and find that allowing for uninsurable income risk and borrowing constraints substantially decreases the power of forward guidance relative to a New Keynesian model with complete markets.

In the standard New Keynesian model with complete markets, an announcement about interest rates has the same effect on current consumption whether it pertains to the current short rate or the short rate 5 years in the future. In contrast, when markets are incomplete the effect of such an announcement on current consumption declines with the horizon of the announcement. Forward guidance about interest rates 5 years in the future has only about 40% as large an effect on current consumption as in the complete markets case, while forward guidance about interest rates 10 years in the future has essentially no effect on current consumption. Intuitively, in the incomplete markets model, a precautionary savings effect counteracts the standard intertemporal substitution motive.

We have focused in the paper on analyzing the response of the incomplete markets model to monetary policy shocks. However, movements in real interest rates play an important role in the response of the economy to a wide variety of shocks. The arguments we have made will therefore affect the response of the economy to a wide variety of shocks.

A Computational Methods

Here we describe the procedure used to find an equilibrium path of the heterogeneous agent model along a perfect foresight transition for the zero-lower-bound episode considered in Section 4.3. The algorithm used to compute the results for a one-time change in the real interest rate is closely related to what we present here.

Writing the firm's first order condition recursively. For the numerical analysis it is convenient to rewrite equation (7) recursively. Define

$$P_t^A \equiv \sum_{s=t}^{\infty} \beta^{s-t} (1-\theta)^{s-t} \left(\frac{P_t}{P_s} \right)^{\mu/(1-\mu)} Y_s \mu W_s \quad (17)$$

$$P_t^B \equiv \sum_{s=t}^{\infty} \beta^{s-t} (1-\theta)^{s-t} \left(\frac{P_t}{P_s} \right)^{1/(1-\mu)} Y_s. \quad (18)$$

then equation (7) becomes

$$\frac{p_t^*}{P_t} = \frac{P_t^A}{P_t^B}. \quad (19)$$

Equations (17) and (18) can be written recursively

$$P_t^A = \mu W_t Y_t + (1-\theta) \beta \mathbb{E}_t (1 + \pi_{t+1})^{-\mu/(1-\mu)} P_{t+1}^A \quad (20)$$

$$P_t^B = Y_t + \beta (1-\theta) \mathbb{E}_t (1 + \pi_{t+1})^{-1/(1-\mu)} P_{t+1}^B. \quad (21)$$

Initial guess. We assume that the economy has returned to steady state after $T = 250$ periods and look for equilibrium values for endogenous variables between dates $t = 0$ to T . In this explanation of our methods we use variables without subscripts to represent sequences from 0 to T . Let X denote a path for all endogenous aggregate variables from date 0 to date T . These variables include aggregate quantities and prices

$$X \equiv \{C_t, L_t, N_t, Y_t, D_t, i_t, W_t, \pi_t, r_t, p_t^*/P_t, S_t, \tau_t, P_t^A, P_t^B\}_{t=0}^T.$$

The dimension of X is given by 14 variables for each date and 251 dates. We require an initial guess X^0 . In most cases we found it sufficient to guess that the economy remains in steady state.

Solving the household's problem. The household's decision problem depends on X through r , W , τ , and D . For a given X^i we solve the household's problem using the endogenous grid

point method (Carroll, 2006). We approximate the household consumption function $c(b, z)$ with a shape-preserving cubic spline with 200 unequally-spaced knot points for each value of z with more knots placed at low asset levels where the consumption function exhibits more curvature. Given the consumption function we calculate labor supply from the household’s intratemporal optimality condition and savings from the budget constraint.

Simulating the population of households. We simulate the population of households in order to compute aggregate consumption and aggregate labor supply. We use a non-stochastic simulation method. We approximate the distribution of wealth with a histogram with 1000 unequally-spaced bins for each value of z again placing more bins at low asset levels. We then update the distribution of wealth according to the household savings policies and the exogenous transitions across z . When households choose levels of savings between the center of two bins, we allocate these households to the adjacent bins in a way that preserves total savings. See Young (2010) for a description of non-stochastic simulation in this manner.

Checking the equilibrium conditions. An equilibrium value of X must satisfy equations (4), (5), (9), (10), (11), (13), (15), (16), (19), (20), and (21) and the monetary policy rule $i_t = \max[0, \bar{r} + \phi * \pi_t + \epsilon_t]$, where ϵ_t is the exogenous deviation from the Taylor rule that takes a negative value under our “extended” policy. Call these 12 equations the “analytical” equilibrium conditions. The remaining two equilibrium conditions that pin down X are that C and L are consistent with household optimization and the dynamics of the distribution of wealth given the prices. Call these the “computational” equilibrium conditions.

To check whether a given X represents an equilibrium of the model is straightforward. We can easily verify whether the analytical equilibrium conditions hold at X . In addition, we can solve the household problem and simulate the population of households to verify that aggregated choices for consumption and labor supply of the heterogeneous households match with the values of C and L that appear in X .

Updating X^i The difficult part of the solution method arises when X^i is not an equilibrium. In this case we need to find a new guess X^{i+1} that moves us towards an equilibrium. To do this, we construct an auxiliary model by replacing the computational equilibrium conditions with additional

analytical equilibrium conditions that approximate the behavior of the population of heterogeneous households but are easier to analyze. Specifically we use the equations

$$C_t^{-\gamma} = \eta_t^1 \beta (1 + r_t) C_{t+1}^{-\gamma} \quad (22)$$

$$C_t^{-\gamma} W_t = \eta_t^2 L_t^\psi. \quad (23)$$

where η^1 and η^2 are treated as parameters of the auxiliary model. For a given X^i , we have computed C and L from the computational equilibrium conditions. We then calibrate η^1 and η^2 from (22) and (23). We then solve for a new value of X from the 12 analytical equilibrium conditions and (22) and (23). This is a problem of solving for 14 unknowns at each date from 14 non-linear equations at each date for a total of 3514 unknowns and 3514 non-linear equations. We solve this system using the method described by Juillard (1996) for computing perfect foresight transition paths for non-linear models. This method is a variant of Newton's method that exploits the sparsity of the Jacobian matrix. Call this solution $X^{i'}$. We then form X^{i+1} by updating partially from X^i towards $X^{i'}$. We iterate until X^i satisfies the equilibrium conditions within a tolerance of 5×10^{-6} .

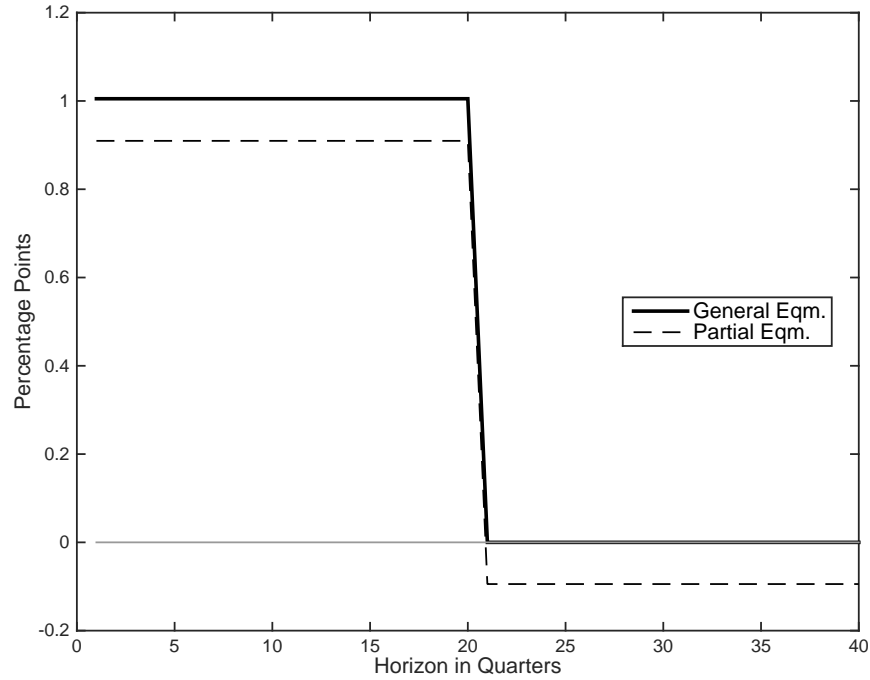

Figure A.1: Comparison of the general and partial equilibrium responses to a one percentage point reduction in real interest rates in period 20 with a unit intertemporal elasticity of substitution under complete markets.

Figure A.2: Comparison of the general and partial equilibrium response to a 50 basis point reduction in real interest rates in period 20 with an intertemporal elasticity of substitution of $1/2$ under incomplete markets. The partial equilibrium response holds wages, profits, and taxes fixed, but allows households to reoptimize their labor supply
